ABSTRACT

The recent discovery of a mutational variant in the *CEP290* gene (*CEP290*: IVS50 + 9T>G), conferring recessive retinal degeneration in Abyssinian and Somali (long-haired Abyssinian) cats (*rdAc*) prompted a survey among 41 cat breeds (846 individuals) to assess the incidence, frequency and clinical consequence of *rdAc*. The *rdAc* allele displayed widespread distribution, observed in 16/43 (37%) breeds, exhibiting a high allele frequency (~33%) in North American and European Siamese populations. Clinical evaluations demonstrated high concordance between *rdAc* pathology and the *CEP290* (IVS50 + 9T>G) homozygous genotype ($P = 1.1E-6$), with clinical disease similar to affected Abyssinians/Somalis. This retinal degeneration has not been reported in breeds other than the Abyssinian/Somali and poses a significant health risk particularly in the Siamese breed group. Alertness of the veterinary community and the present availability of commercial diagnostic testing could synergistically enable breeders to reduce the incidence of *rdAc* blindness in pure-bred cat populations.

Published by Elsevier Ltd.

Introduction

Cat breeds exhibit a high incidence of hereditary disease pathologies (Pontius et al., 2007), as has been seen in other domesticated animal breed populations (Higgins and Nicholas, 2008; Taberlet et al., 2008). Small effective population sizes, the use of popular sires, line breeding and founder effects increase the likelihood of expression of rare pathogenic mutations. Over 280 pathologies with a hereditary component have been reported in the domestic cat.¹ Many conditions are not seen outside of the breed or breed group in which the causative mutation occurred, such as gangliosidosis in the Korat (Baker et al., 2001; Martin et al., 2004; Muldoon et al., 1994) and Type IV glycogen storage enzyme disease in the Norwegian Forest cat (Fyfe and Kurzhals, 1998), possibly due to the constraints that registration rules may place on gene transfer between breeds. Others such as polycystic kidney disease have most likely spread into newer breeds from contributing parental breeds (Persian) (Barthez et al., 2003).

Whilst there have been reports of sporadic retinal pathologies identified in cats (Bistner et al., 1976; Glaze, 2005; Gould and Sargan, 2002; Narfström, 1999, 1983; Rah et al., 2005), hereditary

retinal blindness has not generally been considered a significant health factor in pure-bred cats. With the discovery of an unusually high prevalence (45%) of hereditary rod cone degeneration in the Abyssinian cat approximately 25 years ago in Sweden, it became clear that there was increased risk for hereditary retinal dystrophies causing blindness within some cat breeds (Narfström, 1983, 1985a; Narfström and Nilsson, 1983). Hereditary blindness was observed in a group of American short-haired cats (West-Hyde and Buyukmihci, 1982) and another Abyssinian cat model was subsequently described for retinal blinding disease in the United Kingdom (Barnett and Curtis, 1985; Curtis et al., 1987). More recently, an autosomal recessive form of early onset progressive retinal atrophy has been described in Persian cats (Rah et al., 2005).

The development of critical genetic mapping resources in the cat, including comprehensive genetic maps (Davis et al., 2009; Menotti-Raymond et al., 1999, 2003, 2009; Murphy et al., 2007), the recent 1.9X whole genome sequence of the cat (Pontius et al., 2007; Pontius and O'Brien, 2007) and the generation of a pedigree segregating for *rdAc* (Narfström et al., in press) has enabled the identification of the causal mutation for *rdAc* (Menotti-Raymond et al., 2007b). A single base pair substitution in an intron of the centrosomal protein 290 gene (*CEP290*) (IVS50 + 9T>G) (previously referred to as the *rdAc* allele) results in alternative splicing of the *CEP290* transcript, with subsequent introduction of a premature

stop codon and truncation of the mature protein (Menotti-Raymond et al., 2007b).

Mutations in the homologous human *CEP290* gene are a common cause of human blindness, including approximately 30% of patients with Leber's congenital amaurosis (Hollander et al., 2006). Additionally, mutations in *CEP290* are causative of several rare, severe, early onset syndromic diseases in humans including Joubert's, Senior-Loken, Meckel-Gruber, and Bardet-Biedl syndromes, which cause blindness, mental retardation and kidney failure among other severe clinical signs (Baala et al., 2007; Leitch et al., 2008; Sayer et al., 2006; Valente et al., 2006). None of these additional clinical manifestations are observed in *rdAc* affected cats (Narfström et al., in press).

A recent survey of 21 cat breeds in the USA ($n = 2/\text{breed}$) (Menotti-Raymond et al., 2007b) suggested that the *rdAc* allele was confined to the Abyssinian/Somali (Somali cats are long-haired Abyssinians) and Abyssinian related breeds, including a single *rdAc* allele identified in an Ocicat. This recently generated hybrid breed has had input from both Abyssinian and Siamese cats (Helgren, 1997). Furthermore, a recent genetic survey of Abyssinian and Somali cat populations from the USA, UK, Australia and Scandinavia, identified *rdAc* allele frequencies of 0.07, 0.21, 0.11, 0.20, respectively (Menotti-Raymond et al., 2007b; Narfström et al., in press). In this extended survey the *rdAc* allele genotype was in complete concordance with the presence or absence of retinal atrophy ($P = 3.2E-8$), demonstrating that the *rdAc* genotype is highly predictive of *rdAc* disease progression ($n = 846$).

As the *rdAc* allele has a world-wide distribution in Abyssinian and Somali populations with a significant clinical impact on homozygous affected cats, it became imperative to determine whether the *rdAc* allele is present in additional related breeds. In this report 41 further breeds ($n = 846$ individuals) and 92 outbred (random bred) cats were genotyped at the *rdAc* locus, and 27 individual cats screened for evidence of retinal degeneration.

Surprisingly, the *rdAc* allele was detected in 34% of the cat breeds examined with relatively high frequencies in Siamese and Siamese-related breeds in both North America and Europe. Based on a recent publication on the genetic relatedness of cat breeds (Menotti-Raymond et al., 2007a), we were unable to identify genetic distinctiveness between the Siamese, Colorpoint Shorthair, Oriental Shorthair, Balinese and Javanese breeds, which we will refer to in this study as 'Siamese related breeds' or the 'Siamese breed group'. In addition, the *rdAc* genotype was predictive of the disease phenotype, where all homozygous *rdAc* pure-bred cats that were examined in the study had evidence of retinal degeneration, similar to that observed in Abyssinian and Somali cats. Clearly the *rdAc* mutation has a global distribution in multiple breeds of cats, and this form of heritable retinal degeneration has been previously unrecognized in several popular breeds of cats.

Materials and methods

DNA and tissue samples

DNA samples representing 43 cat breeds and one outbred population were used in the study (Table 1). DNA samples of individuals representing 36 breeds were used from a previous collection (Menotti-Raymond et al., 2005). DNA from five additional breeds was obtained from a population genetic survey (Thai) (see below), the Laboratory of Genomic Diversity DNA resources (Tennessee Rex, Munchkin, Angora) and from a commercial DNA testing laboratory (see below) which included the Peterbald, a breed recently developed with Siamese influence (Fogle, 2001).

DNA from 92 random bred, feral cats was extracted from discarded tissues provided by veterinary hospitals and spay clinics in Frederick and Howard County, Maryland. Additionally, DNA samples ($n = 54$) were obtained from a commercial testing laboratory in Europe LABOKLIN (Bad Kissingen, Germany), including 28 Siamese cats, 1 Balinese, 8 Peterbald, 3 Ocicat, 12 Oriental Shorthair, and 2 Bengal, under the condition of anonymity of the individuals and their owners.

Animals

For cats of recognised breeds, buccal swab samples were obtained, under an approved Animal Care and Use Protocol, from Siamese ($n = 107$), Oriental Shorthair ($n = 40$), Javanese ($n = 4$), Balinese ($n = 11$), and Colorpoint Shorthair ($n = 3$) cats from cat breeders in Maryland, Massachusetts, Pennsylvania, Virginia, Texas and Ohio. Breeders' names were withheld under request for anonymity.

DNA extraction and genotyping of the *rdAc* allele

DNA was extracted from buccal or tissue samples using Qiagen QiAmp DNA Blood Midi and Mini Extraction Kits following the manufacturer's suggested protocols. DNA was quantified using a Hoefer DNA Quant 200 Fluorometer (Amersham BioSciences). A proportion of each sample was diluted to a standard concentration of 2.5 ng/ μ L with sterile distilled water (Quality Biological). Genotyping of the *rdAc* causative single nucleotide polymorphism (SNP) (IVS50 + 9T>G) was performed as described by Menotti-Raymond et al. (2007b).

Clinical examinations

Clinical study of *rdAc* has been extensively characterized in the Abyssinian cat (Narfström, 1983, 1985a,b; Narfström et al., 1989, 2001, 1988; Narfström and Nilsson, 1986, 1989). To determine if the *rdAc* genotype correlated with the development of retinal degeneration pathology as observed in the Abyssinian, a subset of individuals ($n = 27$) from 8 months to 18 years of age, representing six specific breeds in the Siamese breed group (Table 2), were clinically evaluated after genotyping. Ophthalmologic examinations were performed in a masked fashion, in that the veterinary ophthalmologist (KN) examined cats without knowledge of their *rdAc* genotype. Pupils were dilated using short acting mydriatics (Tropicamide 1%, Alcon), and fundic examinations were performed through indirect ophthalmoscopy (Welch Allyn Distributors) in all cats included in the study.

Full-field flash electroretinography (ERG) was performed in a 1-year old Siamese with suspected disease (stage 1) according to the ophthalmoscopic examination and normal age-matched cat, both under medetomidine, 150 μ g/kg, equivalent to 0.15 mL/kg (Domitor, Pfizer) and ketamine anaesthesia (5 mg/kg IM). A portable ERG unit was used (HMsERG, RetVetCorp.) with an automated protocol for evaluation of rod and cone function (Narfström et al., 2002; Katz et al., 2008).

Results

In a genetic survey of 846 pure-bred and 92 outbred cats, the *rdAc* single nucleotide polymorphism (*CEP290*: IVS50 + 9T>G) previously characterized in the Abyssinian and Somali breeds was detected in 14/41 breeds (34%) (Table 1). Frequencies for the *rdAc* allele in the cat breeds from the US ranged from 0.02 (Cornish Rex) to 0.36 (Balinese) (Table 1), although sample sizes were small for some of the breeds and may not accurately reflect the true frequencies. While the *rdAc* allele was also detected in two carriers out of 92 outbred cats sampled in Maryland, the frequency was extremely low (0.01). Whereas, individuals in the Siamese and Siamese-related breeds (Colorpoint Shorthair, Oriental Shorthair, Balinese, Javanese), which will be referred to in this study as the 'Siamese breed group', exhibited the highest allele frequencies for the *rdAc* mutation ranging from 0.27 to 0.36 (Table 1).

A significant part of our study focused on the Siamese breed group, as initial estimates in 36 individuals had demonstrated elevated *rdAc* allele frequencies (data not shown). To confirm these initial estimates within the Siamese and Siamese-related breeds, additional samples were collected from several independent US breed registries ($n = 187$) (Table 3) and European countries ($n = 52$) (Table 1). Samples obtained from 52 cats from six breeds (Balinese, Bengal, Ocicat, Oriental Shorthair, Peterbald, Siamese) from geographically separated countries, demonstrated presence of the *rdAc* allele in 5/6 breeds with elevated frequencies in the Siamese breed group (Table 1).

Within the US additional samples were obtained from populations of Siamese cats maintained in separate registries (CFA, TICA, TCA) (Table 3). Within the TCA registry, breeders have developed two populations of Siamese cats with different conformational standards. Siamese cats which exhibit a rounder head shape and more robust body (reminiscent of the old-style Siamese conformation) are referred to as classic or 'appleheads', and are shown and

maintained as a distinct group from those with a 'wedge-shaped' face. A slim body and more extreme 'wedge-shaped' face has become the standard for most contemporary Siamese cat registries, including the CFA and TICA. No *rdAc* alleles were identified in any of the 31 'appleheads' examined. However, the *rdAc* allele was found at high frequencies in all 'wedge-faced' Siamese, confirming earlier estimates, regardless of registry (Table 3).

A subset of cats from the Siamese and Siamese breed group was examined to determine, if the *rdAc* genotype was predictive of the development of retinal degeneration, as in Abyssinian and Somali cats. Ophthalmic evaluations and functional testing using ERG showed similar changes to those which been described for the Abyssinian cat (Hyman et al., 2005; Kang Derwent et al., 2006; Vaegan and Narfström, 2005, 2008), and it was possible to stage

the disease in these cats according to criteria established in these earlier studies (Narfström, 1985a,b) (Table 2). The age of onset and developmental progression of *rdAc* within these additional cat breeds appears to be similar to the slowly progressive retinal degeneration previously described in *rdAc* Abyssinians, in which affected kittens may have reduced retinal function by 8 months of age with early funduscopic changes detectable at 1–2 years and visual impairment by 5–6 years of age.

Seven individual cats homozygous for the *rdAc* allele, including three Siamese, one Balinese, one Colorpoint Shorthair and two Oriental Shorthair cats, were found to have clinical signs of *rdAc* disease (Table 2). Fig. 1 demonstrates typical funduscopic changes in an 8-year old Siamese cat. ERG recordings resulting from white light stimulation using 10 cd/s/m² in the dark adapted state (Fig. 2) performed in a 1-year old Siamese with stage 1 disease

showed a reduced a-wave in comparison to an age-matched normal cat, while the b-wave in the affected animal was less reduced (43% reduction for the a-wave and 33% for the b-wave, respectively). No signs of retinal degeneration were detected in the 20 remaining cats that were either carriers of the *rdAc* allele or homozygous for the unaffected (wildtype) allele. Complete concordance between *rdAc* genotype and *rdAc* disease status was observed in all 27 individuals examined representing six breeds ($P = 1.1E-6$) (Table 2).

Discussion

The mutational variant in the *CEP290* gene (*CEP290*: IVS50 + 9T>G or *rdAc*) originally identified as the cause of heritable retinal degeneration in Abyssinian and Somali cats has a previously

Fig. 1. Fundus photograph of an 8-year-old Siamese cat homozygous for the *rdAc* mutation in an advanced stage of retinal degeneration. Note the generalized retinal color changes in this submelanotic fundus. There is greyish discoloration horizontally along the visual streak area, hyper-reflectivity in the central fundus and also in the mid-peripheral parts and a generalized vascular attenuation. Courtesy Dr. David A. Wilkie.

unrecognised world-wide distribution in additional cat breeds. In this present study the *rdAc* allele was detected in 14/41 breeds (34%) sampled, with a relatively high frequency found in Siamese and Siamese-related breeds (Table 1). The incidence of *rdAc* affected individuals in outbred populations was negligible, as would be expected for a recessively inherited pathology, with two *rdAc* allele carrier individuals detected from farms in adjacent counties of rural Maryland. The *rdAc* allele was also detected at high frequency in cats from the Siamese breed group residing in Europe, confirming that this mutation is present in geographically separated populations.

Most importantly, all 26 individual cats within the Siamese breed group that were directly examined exhibited complete concordance of *rdAc* genotype with affection status ($P = 1.1E-6$), demonstrating that *rdAc* genotype is an excellent predictor of a cat's *rdAc* affection status. Within this small subset of affected Siamese breed group cats, progression of *rdAc* proceeded in an age-dependent manner, similar to that observed in Abyssinian cats (Table 2). Additional clinical studies will be necessary to confirm these observations in other breeds unrelated to Abyssinians or Siamese in which the *rdAc* allele was detected.

Although sample sizes were small, the *rdAc* allele frequency may be as high as 27–36% in the wedge-faced Siamese breed group of cats from North America (Table 1). If these allele frequencies are confirmed by increased sampling, 7–13% of the individuals in this breed group could be affected with *rdAc*, and would be expected to be severely visually impaired by middle age, at approximately 5–6 years of age. This estimate is based on principals of population genetic theory, specifically the Hardy–Weinberg equilibrium (HWE), which posits that alleles in a population associate randomly unless acted upon by selection (Hartl and Clark, 2006). Certain assumptions about gene flow, genetic drift and non-random mating in populations in the HWE may not apply in populations maintained by the Cat Fancy. However, the *rdAc* polymorphism conformed to HWE within and among each of five Siamese-related breeds ($P > 0.1$) (Table 3).

Fig. 2. ERG tracings from an affected 1-year-old Siamese cat (red) in stage I (stage of suspected disease) and from an age-matched normal cat (blue) showing responses using scotopic high intensity white light stimulation (10 cd s/m^2) and the HMsERG under similar recording conditions for both cats. Note the severely reduced a-wave and the less reduced b-wave in the affected individual in comparison to the normal cat. Amplitude calibration in microvolts and implicit time calibration in milliseconds are shown on the ordinate and on the abscissa, respectively. See also Vaegan and Narfström (2005, 2008).

Of interest was the absence of the *rdAc* allele in our sample set of 'applehead' Siamese which is highly suggestive that these individuals represent a separate gene pool from the wedge-faced Siamese. There is little motivation for breeders to cross between the two widely different phenotypes, resulting in relative isolation. Thus it should not be surprising that there is a significant difference in *rdAc* allele frequency among different registries (see Table 3). The high *rdAc* allele frequency in the wedge-faced individuals could result from a founder effect within the Siamese, which are bred for showing. Additionally, the *rdAc* risk allele could be linked to a gene involved in the distinctive wedge-shaped face phenotype. *RdAc* is not observed in other cat breeds with the distinctive color points of the Siamese (i.e., Birman, Himalayan, Ragdoll), though this linkage was not expected as the gene/gene variants responsible for 'colorpoint' and *rdAc* phenotypes, *tyrosinase* and *CEP290*, respectively, are located on different chromosomes (D1 and B4) (Lyons et al., 2005; Schmidt-Küntzel et al., 2005).

We demonstrate a single SNP in the *CEP290* gene that exhibits high predictability for *rdAc* affection status in multiple breeds. Additionally, we have observed a single DNA haplotype over an approximate 500 kilobase region 5' and 3' of the *CEP290* gene in three breeds (Abyssinian, Siamese, Oriental Shorthair) affected with *rdAc* (data not shown). These data support the hypothesis that the mutation causative of *rdAc* occurred only once, which raises the question of how *rdAc* become so widespread in cat breeds.

The high frequency of *rdAc*, first reported in Abyssinian populations in Sweden (45%) (Narfström, 1983), and the present high incidence in the Siamese breed group, suggest that the *rdAc* mutation originated in either the Abyssinian or Siamese breed group. Based on breeding practice within the Cat Fancy and allele frequency comparisons with other cat populations, it appears most likely that the Abyssinian was the point of origin for introduction into the Cat Fancy. The Abyssinian has anecdotally experienced little genetic input from other breeds, but has itself had input in the creation of several of the modern breeds (Lipinski et al., 2008). Although it cannot be proven, the presence of the allele in the Siamese most likely reflects outcrosses to the Abyssinian sometime after World War II, with selection bias for the more extreme phenotype contributing to the high frequency of the *rdAc* allele in some populations within the Siamese breed group. At the end of WWII, cat breeds in Europe were practically decimated. The long-legged Abyssinian would have been an attractive candidate to 'contribute' to the Siamese breed gene pool.

The absence of the allele in the applehead population study suggests introduction of the *rdAc* allele after the phenotypic split within the Siamese population and argues against the original imports from Siam (now Thailand) as the source for *rdAc* in the Siamese

breed group. We have not found the mutation in other established breeds tracing their origin to Southeast Asia (including the Korat and a large sampling of Burmese), nor in more recent imports from Thailand (Thai) (Table 1), further argument in favor of a more recent introduction into the Siamese.

The majority of modern cat breeds have been developed within the last 100 years, many with genetic input from the Siamese, and some from the Abyssinian (Fogle, 2001; Helgren, 1997). Recently we conducted a study of the relatedness of 38 cat breeds (Menotti-Raymond et al., 2007a). Members of the Siamese breed group exhibited a common genetic pool for markers in the study, facilitating transfer of *rdAc* across these breeds. The majority of the additional *rdAc* affected breeds have had 'input' genetically at some point in the recent past from either the Siamese or Abyssinian breeds, as noted in Table 1 (Fogle, 2001; Helgren, 1997). Founder effects or the use of popular sires in the small effective population sizes of cat breeds can have dramatic impacts on allele frequencies in a relatively short period of time. Our sample numbers are small in some breeds. With a larger and wider sampling, *rdAc* may be identified in other breeds. Additionally, a larger sampling in affected breeds is needed in order to get a more accurate estimate of *rdAc* allele frequency, and perhaps to identify 'lines' that are especially at risk for *rdAc*.

The Siamese cat is one of the most popular breeds. Sporadic reports of blindness in Siamese cats have been made in the veterinary literature (Barnett, 1965; Carlile, 1981; Giuliano and van der Woerd, 1999), but the condition has not been clinically evaluated nor has the magnitude of the problem, as suggested by the present study, been appreciated. Our data suggests that *rdAc* represents a significant problem in the Siamese breed group and a condition that veterinarians should be alert to in a wide range of pure-bred cats.

The fact that *rdAc* has gone undetected across a wide spectrum of cat breeds and appears with a relatively high frequency in the Siamese breed group of cats, is testament to the cats' phenomenal ability to adapt to visual impairment. Pure-bred cats are often maintained in a closed environment of the home and not allowed outside. Given the slowly progressive nature of the disease, generally over several years, affected cats learn to adapt to their decreased visual function. It has been shown in previous studies that the clinical expression of the disease (i.e., visual impairment or blindness) is difficult for cat owners to recognise, since indoor cats can manoeuvre in known surroundings, using their other well developed senses (Narfström et al., in press). In addition, pupillary light reflexes (PLRs), if tested with conventional instrumentation (such as a penlight or a Finhoff transilluminator) appear reactive in affected cats until late in the disease process. However, recent studies have shown that using white and chromatic light stimulation under controlled conditions, and video monitoring, it is possible to observe subtle changes in the PLRs of affected cats already in the early stage of disease (S. Thompson et al., unpublished data).

With a concerted effort between veterinarians and breeders to diagnose and test for *rdAc* induced retinal degeneration, this condition can be reduced in pure-bred cat populations. In the early 1980s *rdAc* had an extremely high incidence of approximately ~45% in the Swedish Abyssinian population. The current incidence of individuals affected with *rdAc* has decreased to approximately 4% through a concerted effort among breeders reporting carrier individuals (Narfström et al., in press). Two commercial animal testing laboratories provide genotyping for the *rdAc* causative SNP. As *rdAc* is a recessive condition, testing is recommended in the breeding population, particularly in the Siamese breed group. Cooperation and alertness on the part of the cat breeder and veterinarian community could work to reduce significantly the incidence of *rdAc* in cat breed populations.

Conclusions

These results demonstrate that the mutational variant (*CEP290*: IVS50 + 9T>G), causative of *rdAc*, so far unreported in breeds other than the Abyssinian/Somali, displays widespread distribution among cat breeds and exhibits a high allele frequency (~33%) in both North American and European Siamese cat populations. Clinical evaluations demonstrate high concordance between *rdAc* pathology and the presence of a homozygous genotype for the *rdAc* risk allele. This retinal degeneration poses a significant health risk particularly in the Siamese breed group. Alertness of the veterinary community and the present availability of commercial diagnostic testing could synergistically enable breeders to reduce the incidence of *rdAc* blindness in pure-bred cat populations.

Conflict of interest statement

None of the authors of this paper has a financial or personal relationship with other people or organizations that could inappropriately influence or bias the content of the paper.

Acknowledgements

We wish to thank all of the cat breeders who donated buccal swab samples for this study. Names have been withheld under the desire for anonymity. We thank Dr. David Wilkie for the photograph used in Fig. 1. We additionally thank LABOKLIN for their contribution of 54 pure-bred cat DNA samples. We also wish to thank Donald Crouser DVM of the Boston Road Animal Hospital, Springfield, MA, USA for the contribution of his time facilitating ERG procedures.

This project has been funded in whole or in part with federal funds from the National Cancer Institute, National Institutes of Health, under contract N01-CO-12400. The content of this publication does not necessarily reflect the views or policies of the Department of Health and Human Services, nor does mention of trade names, commercial products, or organizations imply endorsement by the US Government.
